

Objective: Build a console application that calculates a customer's total while practicing **User Inputs** , **Variables** , **Operators** , and **Type Casting**.

1. The Scenario

You are building the checkout logic for a local shop. The shop owner wants to offer a fixed discount but has a quirky rule: the final price is always **rounded down** to the nearest whole number (integer) as a "loyalty bonus" for the customer.

2. Requirements & Logic

Your program must implement the following steps using **Basic Syntax**:

- **Step 1:** Use the Scanner class to collect three pieces of data from the user:
 - o String product name.
 - o double unit price.
 - o int quantity.
- **Step 2:** Define a **final** variable for the discount rate (e.g., 15% or 0.15).
- **Step 3:**
 - o **Subtotal:** $subtotal = unit_price \times quantity$
 - o **Discount Amount:** $discount_amount = subtotal \times discount_rate$
 - o **Final Price** (before rounding): $final_price = subtotal - discount_amount$
- **Step 4:** Use **Explicit Casting** to convert the final_price from a double to an int.
- **Step 5:** Use **Concatenation** to print a professional-looking receipt to the console

3. Expected Output

```
--- Welcome to the {Your Name} Shop ---
```

```
Enter Product Name: Gaming Mouse
```

```
Enter Unit Price: 25.75
```

```
Enter Quantity: 3
```

```
--- Final Receipt ---
```

```
Item: Gaming Mouse
```

```
Subtotal: $77.25
```

```
Discount Applied: $11.5875
```

```
Total (Rounded Down): $65
```

```
-----
```

[NOTE: You are allowed to apply improvements or any other techniques you want to. These are minimum requirements]
